Steal Tree: Low-Overhead Tracing of Work Stealing Schedulers
Jonathan Lifflander (UIUC), Sriram Krishnamoorthy (PNNL), Laxmikant V. Kale (UIUC)

Introduction
Work stealing is a popular approach to scheduling task-parallel programs, used in many programming models including OpenMP 3.0, Java Concurrency Utilities, Intel TBB, Cilk, and X10. The flexibility inherent in work stealing when dealing with load imbalance results in seemingly irregular computation structures, complicating the study of its runtime behavior. We present an approach to efficiently trace async-finish parallel programs scheduled using work stealing.

Tracing Algorithms
Rather than trace individual tasks, we exploit the structure of work stealing schedulers to coarsen the events traced. In particular, we construct a steal tree: a tree of steal operations that partitions the program execution into groups of tasks. We identify the key properties of two scheduling policies that enables the steal tree to be compactly represented.

Primary Contributions
- Identifying the key properties of work-first and help-first schedulers to compactly represent the stealing relationships.
- Algorithms that exploit these properties to trace and replay async-finish programs by efficiently constructing the steal tree.
- Demonstration of low space overheads and within-variance perturbation of execution in tracing work stealing schedulers.

Applications
- We show a substantial reduction in the cost of data race detection using an algorithm that exploits our traces to maintain and traverse the dynamic program structure tree (DPST). In some cases, we observe up to a 70% reduction in tree traversals.
- Using our traces we are able to reduce the memory requirements for retentive stealing by not explicitly enumerating tasks.
